**Abstract.** Synthetic dyes can cause health and environmental impacts. Thus, there are opportunities to develop natural dyes, one of which is produced by *Indigofera tinctoria* plants. This plant is from Fabaceae that has the potential to produce a natural blue color. Natural dyes are extracted from the leaves of plants that contain indigo compounds. Indigo growth and precursors are very dependent on environmental conditions, one of which is light intensity. This study aimed to study the morphological and physiological plant responses in *I. tinctoria* to several levels of light intensity. The research was conducted in Puron Village, Sukoharjo, Indonesia with a complete randomized block design (RCBD) one factor, namely the level of light intensity (100 %, 50 %, and 25 %) with nine replications. Light intensity affected the morphology and physiology of *I. tinctoria*. Plants responded to low light intensity by increasing the leaf area index, specific leaf area and plant height. Leaf area, specific leaf area and plant height were highest at 25 % intensity. However, the number of leaves and nodes got greater at full light intensity. Higher light intensity increased the chlorophyll content a, b and total, thus, higher biomass yield which was 18.86 g at the age of 8 wk.

**Keywords:** Chlorophyll, leaf area, number of nodes, plant height, specific leaf area.

## 1 Introduction

Textile industries use synthetic dye for dying medium. Synthetic medium has some benefits in terms of characteristics; bright color, easily dissolves in water, cheaper to produce, and easier to apply on fabric [1]. Thus, the waste from these industries contains various types of synthetic dyes. The waste is considered a pollutant [2]. The waste treatment process is not yet efficient. It can cause serious environmental problems in connection with the reuse of wastewater for irrigation. Applying proper treatment process is very important in order to minimize pollution, one of which is by developing the production of the *Indigofera tinctorial* L. plant to be used as natural dyes.

*I. tinctoria* is from the Fabaceae family, which is efficacious as a natural dye industry. The plant is used as a natural dye agent in the textile industry because it contains indigo pigments that produce indigo colors [3]. *I. tinctoria* natural dyes were the main product of India and West Africa before the discovery of synthetic indigo. Natural dye compounds are extracted from plant leaves. These plant cells contain indican secondary metabolites (indoxyl- $\beta$ -D-glucoside) and/or B (1H-Indol-3-yl  $\beta$ -D-ribo-3-hexosulopyranoside) precursors. Indican is synthesized in chloroplasts and stored in vacuoles.

Indigo growth and precursors are highly dependent on environmental conditions, one of which is light intensity. In Europe, this plant can adapt well but is not resistant to drought, and indigo content is positively influenced by the intensity of sunlight [4]. Light is the main environmental component that affects the survival rate, morphological characteristics, photosynthetic characteristics, and primary and secondary metabolism of plants [5]. Light is a vital resource for plants, and light deficiency can directly change the development of the photosynthetic apparatus of plant photosynthetic capacity [6]. Most pigments that are specifically bound to thylakoids and the photosynthetic system are strongly influenced by the availability of light. This research aimed to study the morphological and physiological responses of *I. tinctoria* to several levels of light intensity.

## 2 Materials and methods

The research was conducted from April to August 2019 in Puron Village, Bulu, Sukoharjo, Central Java, Indonesia. The research location was at 77.745 S and 110.83 E with an altitude of 120 m.a.s.l. Microclimatic conditions with an average precipitation of 2 289 mm yr<sup>-1</sup> and the number of rainy days 105 d. Daily average temperature of 25 °C to 27 °C, humidity around 80 %. The study used a complete randomized block design (RCBD) with one factor, the light intensity with three levels; 100 %, 50 %, and 25 %. All treatment was replicated with nine replications, so there were 27 experiment units. The planting material used was *I. tinctoria* seeds, which are green in color. The tool used as an application of light intensity was a shading net with various density levels.

Chlorophyll analysis was carried out at *Laboratorium Fisiologi Tumbuhan* Universitas Sebelas Maret using the Arnon [7] method with a slight modification. Chlorophyll a and b uptake was measured using a UV-Visible Double-ray Spectrophotometer (Eliso SI-156, India) at 663 and 645 nm by using acetone 90 % as the blank. Plant physiology variables observed were chlorophyll a, b, and total, the biomass of plants aging 6 wk, 8 wk, and 10 wk. Morphological variables recorded were plant height, number of leaves, number of branches, leaf area, specific leaf area (LW/LA: LW = leaf weight, and LA=leaf area). The data were analyzed using analysis of variance with  $\alpha$  5 % (95 % confidence level) followed by a 5 % Duncan's Multiple Range Test (DMRT) if between the experimental units were significantly different.

Environmental variables observed were light intensity at 7 a.m., 12 p.m., and 5 p.m. (GMT+7) using lux meter (Mextech, China), temperature, and humidity using Thermo hygrometer (Shanghai, China). Observations of the environment were carried out 12 times, starting at the age of 7 d plants until harvest time. Observation of light intensity was carried out on the canopy of *I. tinctoria* ie, under the third leaf from above.

**Table 1.** Average environmental variables in the research location

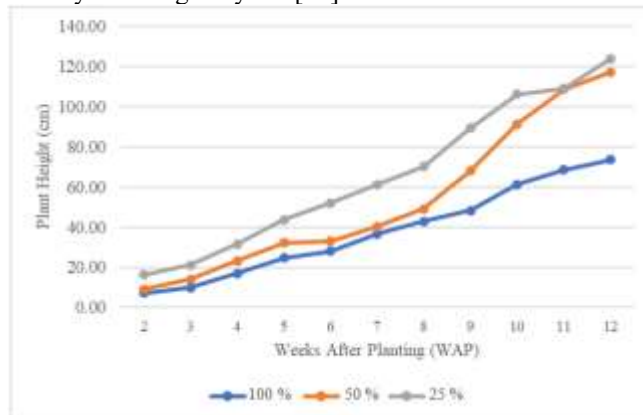

Light intensity	Variable	Time of observation (GMT+7)		
		7 a.m.	12 p.m.	5 p.m.
100 %	Light intensity (lux)	48 600	63 200	16 010
	Temperature (°C)	27.8	36.7	29.6
	Relative humidity (%)	64	46	54
50 %	Light intensity (lux)	24 600	32 400	8 430
	Temperature (°C)	27	34.2	28.9
	Relative humidity (%)	63	41	56
25 %	Light intensity (lux)	13 600	5 300	4 025
	Temperature (°C)	26.4	32	28.3
	Relative humidity (%)	66	50	57

### 3 Results and discussions

#### 3.1 Morphological responses of *I. tinctoria* to light intensity

Plant morphology has manipulability and adaptation mechanisms in changing environmental conditions [8]. Light intensity significantly affected the growth of *I. tinctoria* plants at 2 wk to 12 wk old (Figure 1). Different light conditions had different effects on plant height. Plants grew higher with lower light intensity levels. This condition indicated that the stem of the *I. tinctoria* plant was etiolated. This is in accordance with the research of [9] that shading caused an increase in the height of soybean plant stems. Low light caused the internodes to grow longer [10]. Adaptation of plants to low light intensity would affect the morphology, anatomy, and physiology of plants, including an increase in leaf area and plant height as an effort to reduce the use of metabolites, and reduce the light transmitted and reflected [11].

*I. tinctoria* plant height at full light intensity was only 73.44 cm, while at 50 % intensity, the plant height increased by 37.34 %, which reached 117.22 cm and increased 40.72 % at 25 % intensity. Plants responded to stem elongation and inhibited the growth of stem diameter to absorb a high amount of light [12]. This was due to the low light, which activated auxin and further caused symptoms of etiolation [13]. Shading application led to carbon allocation towards stems elongation at the expense of roots and leaves development, thereby affecting the yield [14].

**Fig. 1.** Effect of light intensity on plant height

Leaves are considered as the head part of the plant. Leaf functions to collect light energy from the sun and play a role in photosynthesis to convert light energy into biochemical energy [15]. The number of leaves was considered a major factor that determined the quality of growth and the ability of plant photosynthesis. The results showed that the number of *I. tinctoria* leaves reached 368 strands in full light intensity at 12 WAT (Table 1). The number of leaves at each intensity showed significantly different results. The number of leaves at 50 % light intensity decreased by 39 % reached 225 strands and at 25 % light decreased by 51.79 %. The growth of nodes also decreased at a low light intensity. The results showed that the number of nodes at each intensity was significantly different. The number of nodes in full light reached 28 nodes. In 50 % intensity number of media is reduced by 41.69 % reached only 16 nodes. Plants responded to low light by extending internodes and leaf stalks, resulting in reduced nodes. Thus, the number of leaves was also reduced. Light intensity-modulated the content of the thylakoids as the PSII/PSI ratio, the number of reaction centers. Plants in low light exhibited lower levels of photosystem II (PSII), number of reaction centers, as well as the decreased capacity for oxygen evolution, electron transport, and limitations in electron transport between PSII and PSI [16]. An important effect of low light was the reduction in clean photosynthesis [17]. Decreased photosynthesis occurred from two main mechanisms: i) a decrease in diffusion of CO<sub>2</sub> into leaves, due to decreased inter-cell CO<sub>2</sub> and stomatal conductance, and ii) potential inhibitory metabolism for photosynthesis by inhibiting leaf growth and enlargement by controlling cell proliferation [18].

Leaf area shows the ability of plants to carry out photosynthesis because it is associated with the use of light and the use of growing facilities [19]. The results of this study indicated that light intensity significantly influenced the area of *I. tinctoria* leaves. Leaf area reached 40.22 at 25 % light; at 50 % light, the leaf area was reduced by 19 % and reduced by 61 % at 100 % light. It showed that plants responded to low light by increasing leaf area. Reduced light supply encourages an increase in leaf area [20], which is an attempt by plants to increase the area of light absorption and light capture efficiency [21]. The optimum leaf area shows that sunlight is received evenly by the leaf [22].

The specific leaf area (SLA) at 50 % light was 63.98 cm<sup>2</sup> g<sup>-1</sup>, 19 % higher than full light, and 2.1 % higher than 50 % light. Specific leaf area at light 25 % and 50 % did not show significantly different. Such a situation also appeared in soybean crop yielded in the research of [6] that SLAs were increased in low light. An increase in specific leaf area due to phototropism [23, 8]. However, an increase in SLA was not able to compensate for the decrease in leaf area caused by reduced light interception. Tolerant of intolerant species to low light would optimize the capture and utilization of the light by increasing SLAs [14], because SLA was an important parameter that reflected plant growth and carbon assimilation and was strongly influenced by changes in light conditions [24, 25].

**Table 2.** Light intensity on the growth of *I. tinctoria*

Light intensity (%)	Number of leaves (strand)	Leaf area	Specific leaf area (cm <sup>2</sup> g <sup>-1</sup> )	Number of nodes
100	368.56b	15.65a	46.10 a	28.78b
50	225.00a	32.24b	65.36 b	16.78ab
25	177.67a	40.22c	63.98 b	13.11a

### 3.2 Physiology plant response in *I. tinctoria* to light intensity

The light intensity had a significant effect on chlorophyll (Table 4). The amount of chlorophyll at a full light intensity and 50 % were not significantly different, at 25 % intensity showed significantly different and decreased by 6 %. Light intensity on chlorophyll b and total chlorophyll had no significant difference. Chlorophyll b and total decreased at a low light intensity. The decrease in chlorophyll b in light of 25 % was 2.4 %, the decrease in total chlorophyll was 4.5 %. These results indicated that low light decreased chlorophyll a, b and total in *I. tinctoria*. These results are in accordance with the results of the study of [26] that decreasing the shading from T75 to T0 increases the content of Chl a, Chl b, and Chl a + b in soybeans. Chlorophyll content also showed a decrease in water spinach planted under shading net [27]. Under changing light conditions, studies of Chl a, Chl b, and Chl a + b help as an index for sunlight absorption [28]. The amount of Chl was significantly affected by changes in light availability and decreased with the reduction in light [29]. Chlorophyll content acts as an important factor in determining plant photosynthesis [30]. Increased Chl b increases light interception under shading stress [31]. The amount of chlorophyll in shade-resistant plants increases under shading [32]. His research shows that the shade increases the content of chlorophyll a, b, and total and photosynthetic activity. This may indicate that the *I. tinctoria* plant is intolerant of low light.

**Table 3.** Light Intensity toward chlorophyll content of *I. tinctoria*

Light intensity (%)	Chlorophyll		
	A	b	total (a+b)
100	0.519 b	0.867 a	1.386 a
50	0.512 ab	0.846 a	1.358 a
25	0.487 a	0.840 a	1.327 a

*I. tinctoria* biomass increased as plant aged. The light intensity did not significantly affect the biomass of *I. tinctoria* at 6 WAP. Low light showed the greatest biomass at 6 WAP. Plant biomass at 6 WAP at each light intensity level was not significantly different. According to Yao et al. [32], leaf area is an important factor affecting plant light and biomass interception. The yield of plant biomass at 6 WAP had a linear relationship with the leaf area that the highest biomass resulted in light 25 %. A significant linear relationship between leaf area and biomass per plant in shady conditions [33]. This is because the reduction in leaf area directly impacts the reduction in photosynthate production. Some studies have shown that increasing the leaf area increased the rate of net photosynthesis [34]. However, this was incompatible with the *I. tinctoria* biomass at 8 WAP and 10 WAP that at full light, the leaf area was low, and biomass production was high. [19] stated that the decrease in SLA would be offset by an increase in crop dry weight. Plants with low SLA value would have narrower and thicker leaves but have a great dry plant production. This study showed that light intensity affected biomass at 8 and 10 WAP, full light could produce the greatest amount of biomass that was 18.86 at 10 WAP, 27 % greater than light 25 % and 18 % greater than biomass at 50 % light. These results indicated that the biomass of *I. tinctoria* increased in full light. This is because biomass was a product of photosynthesis that depended on the availability of light to produce carbohydrates. Plants that received low light modified the number of nodes to be very low and stimulated the plant stem internodes, causing reduced leaves to grow and reduced the number of nodes resulting in reduced biomass production. Adapting the mechanism of plants in various light environments was by changing the characteristics of photosynthesis. The rate of net photosynthesis decreases, resulting in a reduction in plant biomass in low light [35]. This is in accordance with the results of [36] research that biomass production has a linear

relationship with the chlorophyll content of plants, ie the production of biomass and chlorophyll content decreases at low light. Low light intensity caused an increase in plant height, leaf area, and specific leaf area (SLA). These morphological changes allowed relatively more light interception and increased the efficiency of light use in *I. tinctoria* due to the shading effect.

**Table 3.** Light intensity on biomass production

Light intensity (%)	Biomass (g)		
	6 WAP	8 WAP	10 WAP
100	10.21 a	16.04 b	18.86 b
50	11.09 a	14.30 ab	16.37 ab
25	14.47 a	11.70 a	13.65 a

## 4 Conclusion

Light intensity affected the morphology and physiology of *I. tinctoria*. Plants responded to low light intensity by increasing plant height, leaf area index, specific leaf area. Leaf area, specific leaf area, and plant height were highest at 25 % intensity. An increase in leaf area had a linear relationship with biomass at 6 WAP that the highest biomass production at light 25 %. However, biomass production at 8 WAP and 10 WAP was strongly influenced by high light reaching 18.83 g. An increase in biomass was due to the number of leaves, the higher number of nodes in full light. Light intensity affected chlorophyll, the chlorophyll content increased in high light, thus, providing materials and energy base for photosynthesis.
